University of Birmingham, Depart. Civil Engineering, UK

## Abstract

In this paper an experimental study on eight simply-supported and four two-span continuous beams employing austenitic and duplex stainless steel rectangular hollow sections (RHS) is reported. In parallel with the tests, finite element models were developed. Upon validation against the experimental results, parametric studies were conducted to expand the available structural performance data over a range of cross-section slendernesses, structural systems and load configurations likely to occur in practice. The obtained experimental and numerical results were used to assess the accuracy of EN 1993-1-4 deign provisions and to explore the possibility of plastic design for stainless steel indeterminate structures, simultaneously accounting for the effect of strain-hardening at cross-sectional level and moment redistribution exhibited by structures employing stocky cross-sections.

## Keywords

Stainless steel structures; Continuous beams; Plastic design; Eurocode 3; Continuous Strength Method (CSM)

# 1 Introduction

The excellent atmospheric corrosion resistance and favourable mechanical properties of stainless steel make it well suited for a range of structural applications, particularly in aggressive environments or where durability and low maintenance costs are crucial design criteria<sup>[1, 2]</sup>. The main disadvantage hindering the more widespread usage of stainless steel in construction is its high material cost and price volatility. However, life-cycle costing<sup>[3]</sup> and sustainability considerations<sup>[4]</sup> make stainless steels more attractive when cost is considered over the full life of the project, due to the high potential to recycle or reuse the material at the end of life of the project.

The design of stainless steel structures is covered by a number of international design codes<sup>[5-8]</sup>, which have either recently been introduced<sup>[8]</sup> or were recently amended<sup>[5-7]</sup> in light of recent experimental tests, thus indicating the worldwide interest stainless steel has received in recent years. Despite the absence of a well-defined yield stress, all current design standards for stainless steel adopt an equivalent yield stress and assume bilinear (elastic, perfectly-plastic) behaviour for stainless steel as for carbon steel in an attempt to maintain consistency with traditional carbon steel design guidance. Neglecting the significant strain-hardening inherent in stainless steel has been shown to lead to overly conservative design, particularly for stocky stainless steel components<sup>[9-13]</sup>. Given the high material cost of stainless steel, improving existing design guidance is warranted. Improvements can be made either by calibrating the existing design procedures, some of which are based on engineering judgment and limited test data, against additional experimental results, or by devising more accurate design approaches in line with actual material response. In any case more efficient yet safe design rules are desirable. To this end, the classification limits for stainless steel elements have been revised on the basis of a collection of all available test results<sup>[14]</sup> and were included in the recently amended version of EN 1993-1-4<sup>[5]</sup>. Moreover the development of the Continuous Strength Method<sup>[15]</sup> as a rational means to account for the significant strain-hardening exhibited by stocky sections in design led to its incorporation as an alternative design approach in [7]. Similarly, research on the structural response of slender stainless steel sections has led to the extension of the Direct Strength Method to stainless steel compression members<sup>[16]</sup>.

The majority of published research articles on stainless steel structures focus on the response of individual members. All published literature on the behaviour of stainless steel indeterminate structures is limited to only four publications<sup>[17-20]</sup>, which investigate the structural response of two-span continuous beams subjected to point loads. It was established that for austenitic and duplex stainless steels both strain hardening at cross-sectional level and moment redistribution for indeterminate structures employing stocky sections have to be allowed for in design and that the current design guidance severely underestimates the load carrying capacity of stainless steel indeterminate structures employing Class 1 sections by 40% on average<sup>[19]</sup>. Hence, due to insufficient relevant experimental data, no rules are given for plastic global analysis of indeterminate stainless steel structures in any current structural design code, even though the ductility of stainless steel is superior to that of ordinary structural steel. Large inelastic rotations and large strains can clearly be accommodated by sufficiently stocky stainless steel sections<sup>[9,11,13]</sup>.

The controversy of not allowing plastic design for an indeterminate structure made of a ductile material is obvious in [5] where it is explicitly stated that "No rules are given for plastic global analysis" even though a slenderness limit for Class 1 elements is specified in the same code. Deficiencies in current design guidance puts stainless steel at a disadvantage compared to other materials thereby hindering its use in applications where it might be the preferred solution, had the design standards not imposed strict restrictions to its design due to a gap in current knowledge. To address the lack of design guidance on global plastic design of stainless steel structures, a research project investigating the response of stainless steel continuous beams and frames is currently underway at the University of Birmingham. This paper reports a series of tests on simply supported beams, which are utilized to establish the cross-sectional response under bending both in absence and in the presence of moment gradient and a series of tests on continuous stainless steel beams. In parallel,

finite element models were developed and validated against the experimental results and parametric studies were conducted to expand the available structural performance data over a range of cross-section slendernesses, structural systems and load configurations likely to occur in practice. The obtained experimental and numerical results were used to assess the accuracy of EN 1993-1-4<sup>[5]</sup> and to explore the possibility of plastic design for stainless steel continuous beams.

# 2 Experimental Studies

Physical tests were carried out on simply supported beams loaded in the 3-point bending and in the 4-point bending configuration and on two-span continuous beams loaded with point loads at their mid-span in the Structures Lab at the University of Birmingham. In addition, tensile tests on flat and corner coupons extracted from the finished cross-sections were carried out in the lab of the department of Metallurgy and Materials at the University of Birmingham.

# 2.1 Chosen cross-sections

Four RHS with a nominal outer web depth H and a nominal outer flange width B equal to 100 mm and 50 mm respectively were employed in the experimental study reported herein. The employed sections cover not only a wide range of local slendernesses, but also different material grades and production techniques. Three of the sections were cold-formed from Grade EN 1.4301/1.4307 austenitic stainless steel and had a nominal thickness t of 2 mm, 3 mm and 5 mm. The fourth section was fabricated by welding two parallel flange channel sections cold-formed from Grade 1.4462 duplex stainless steel along the flange tips and had a nominal thickness of 3 mm. Hence the austenitic cold-formed RHS had a seam weld along the centreline of one of the webs (i.e. longer faces), whilst the fabricated duplex RHS had a longitudinal weld along the centreline of each flange. It is noteworthy that the welded duplex section was fabricated due to difficulties associated with sourcing cold-formed duplex stainless steel RHS in small quantities (as required for a research project), whilst austenitic stainless steel RHS were readily available. Moreover, despite the lower nickel content which is expected to lead to a lower price<sup>[21]</sup>, lean duplex stainless steels were even more expensive than their ordinary duplex counterparts, unless a large quantity was requested. Clearly several issues with the supply chain need to be addressed to take advantage of the benefits of such novel structural materials. Prior to testing careful measurements were taken for each beam specimen. Since all beam specimens for each section were cut from the same length of tubes, the measurements were averaged for each nominal cross-section and are reported in Table 1, where r<sub>i</sub> refers to the internal corner radius and the remaining symbols have been previously defined. The subscript D following the section designation denotes the specimen in duplex stainless steel.

# 2.2 Material coupon tests

Two flat material coupons (i.e. one from the mid-width of the web and one from the mid-width of the flange) and one corner coupon were extracted from each of the four cross-section considered herein and were tested according to EN ISO 6892-1<sup>[22]</sup>. For the austenitic sections, the flat coupons did not contain the weld, whilst for the duplex section one of the flat coupons contained the weld along the coupon length. The obtained results are summarized in Table 2, where E is the Young's modulus,  $\sigma_{0.2}$  is the 0.2 % proof stress,  $\sigma_{1.0}$  is the 1.0 % proof stress,  $\sigma_u$  is the ultimate tensile stress,  $\epsilon_f$  is the plastic strain at fracture and n and  $n_{0.2,1.0}$  are material parameters used in the two-stage Ramberg-Osgood<sup>[17,23,24]</sup> material model, which is adopted in the numerical modelling as discussed in the next section. Typical stress-strain curves are depicted in Fig.1 for the RHS 100×50×2 and the duplex RHS 100×50×3 material coupons, where the corner coupons are seen to possess enhanced material strength.

The key material properties stated in the mill certificates for the sheet material used for the fabrication of the crosssections are summarized in Table 3. As expected the proof stress and ultimate stress values corresponding to coupons extracted from the finished sections are significantly higher compared to the mill certificate values for the austenitic crosssections, since during the cold-forming production process the coil material properties are significantly enhanced<sup>[25]</sup>. A far inferior level of enhancement can be observed for the duplex cross-sections, arguably due to the different fabrication process.

# 2.3 Tests on simply supported beams

For each of the four cross-sections, one beam was tested in the 3-point bending configuration and one in the 4-point bending configuration to study the response in major axis bending. The test arrangement and employed instrumentation for the 3-point bending tests is schematically shown in Fig.2, whilst the overall setup is depicted in Fig.3. All specimens had a total length of 1500 mm and the simply supported conditions were achieved with the use of steel rollers, which allowed both the rotation about the axis of bending and the axial displacement at the ends of the beams. The rollers were placed 75 mm inwards from each beam end, as a result the span of the beams was 1350 mm as shown in Fig.2. In order to prevent web crippling<sup>[26]</sup>, wooden blocks which were closely matching the dimensions of the tested beams, were inserted into the tubular specimens at the loading point and the supports.

All beams tested in the 3-point bending configuration were loaded at mid-span by a hydraulic actuator at a rate of 1.5mm/min. Two inclinometers were placed at the supports, as shown in Figs. 2 and 3, in order to measure the end-rotations of the three point bending tests. For each specimen, two strain gauges were attached, one at the top and one at the bottom flange, at a distance of 50 mm from the loading point, in order to measure the extreme tensile and compressive

strains that occur during the bending tests. Moreover, one LVDT was located at the loading point of the 3-point bending tests, in order to measure the vertical deflection of the mid-span. The Squirrel data logger was used for recording the load, strains, end-rotations and mid-span displacements at 2 sec intervals.

The 4-point bending test arrangement was similar to the 3-point bending one, as shown schematically in Fig.4. Two equal point loads were applied at a distance equal to one-third of the clear span length from each end support via a spreader beam, which was positioned between the loading jack and two steel rollers, resting on the top flange of the specimens at the loading points and loaded at mid-span via a hydraulic actuator. As with the 3-point bending tests, wooden blocks were inserted within the tubes at the two loading points and supports to prevent web crippling.

In Fig. 5 the moment-rotation and moment-curvature response of all specimens are depicted for the 3-point bending and 4-point bending tests respectively. To facilitate the comparison between the responses exhibited by the tested sections, the curves are displayed in a non-dimensional format, where the moments are normalized by the plastic moment resistance  $M_{pl}$  and the rotations  $\theta$  and curvatures k are normalized by the elastic part of the rotation  $\theta_{pl}$  or elastic part of the curvature  $k_{pl}$  corresponding to  $M_{pl}$  respectively, which are obtained from Equations 1 and 2.

$$\theta_{\rm pl} = \frac{M_{\rm pl}L}{2\rm EI} \tag{1}$$

$$k_{\rm pl} = \frac{M_{\rm pl}}{\rm EI} \tag{2}$$

Key experimental results, including the moment resistance  $M_u$ , the ratios of the ultimate moment to the elastic and plastic moment resistance ( $M_u/M_{el}$  and  $M_u/M_{pl}$  respectively) and the rotation capacity R are reported in Table 4. The rotation capacity is defined by Equation 3, where  $\theta_u$  ( $k_u$ ) refer to the total rotation (total curvature) at mid-span when the moment-rotation (moment-curvature) curve falls back below  $M_{pl}$  and are obtained from the tests. No rotation capacity is defined for specimens failing prior to reaching  $M_{pl}$ . All failed specimens are depicted in Fig. 6. All failure modes relate to local buckling of the compression flange and the upper part of the web.

$$\mathbf{R} = \frac{\theta_{u}}{\theta_{pl}} - 1 ; \qquad \mathbf{R} = \frac{k_{u}}{k_{pl}} - 1$$
(3)

#### 2.4 Tests on continuous beams

In order to determine the redistribution capacity of austenitic and duplex stainless steel continuous beams, four two-span structural configurations were subsequently conducted on the same cross-section sizes and material employed for the simply-supported beams. All specimens had a total length of 3000 mm. Preliminary investigations were conducted in order to find a loading configuration that would allow significant moment redistribution, without repeating the structural arrangements examined in past publications<sup>[17-20]</sup>. It was decided to configure two equal spans with the one being doubly loaded compared to the other (i.e. one span loaded with a concentric load "P/3" and the other one with "2P/3", where P the reference total load), considering the case of major axis bending only.

The continuous beam test arrangement is shown schematically in Fig.7. The simply supported conditions were achieved with the use of steel rollers at the three supports. The clear span between the supports was 1425 mm. The instrumentation included two load cells, four inclinometers, four strain gauges and two LVDTs. The load cells were used to measure the reaction forces. The inclinometers were used to measure the rotations in the two end supports and in the two sides of the central support. The strain gauges were affixed at a distance 50 mm from the mid-span and from the "2P/3" loading point and their readings were used to ensure that no axial restraint was provided by the end rollers. The LVDTs were used to record the two vertical mid-span displacements. Similarly to the simply-supported beams, in order to prevent web crippling failure wooden blocks were inserted in the tubular specimens at the loading points and the supports. In order to prevent local bearing failure, steel blocks of 15 mm thickness were used for the application of the load and at the end rollers. A spreader beam eccentrically loaded, as shown in Fig.7, was used to ensure the required loading configuration. The load was assigned vertically with a loading rate of 1.5 mm/min. The Squirrel data logger was used for recording the load, strains, end-rotations, reaction forces and mid-span displacements at 2 sec intervals. A photograph from the overall set up is given in Fig.8.

The key results are summarized in Table 5, where  $F_u$  is the experimental load at collapse,  $\delta_u$  is the vertical displacement at "2P/3" loading point at collapse,  $\theta_u$  is the end-rotation of the most heavily loaded span at collapse and  $F_{coll}$  is the theoretical plastic collapse load evaluated in line with classical plastic analysis procedures, considering rigid-plastic material response. As anticipated, all specimens failed by developing a distinct plastic hinge at "2P/3" loading point, followed by a second plastic hinge at the central support. The experimental response is shown in Fig. 9(a), where the load is plotted against the vertical displacement at "2P/3" loading point for all four specimens. The load normalized by the  $F_{coll}$ is plotted against the maximum end-rotation in Fig. 9(b). The evolution of the support to span moment ratio ( $M_{supp}/M_{span}$ ) against the increasing vertical displacement at "2P/3" loading point is shown in Fig. 9(c) for the most slender and the stockiest specimen. The horizontal lines of 1.29 and 1.0 correspond to the theoretical moment ratios of the elastic and rigid plastic analysis respectively and the vertical lines pass through the displacement at which the ultimate load occurred. As can be seen for the stockiest  $100 \times 50 \times 5$  specimen, the moment ratio is equal to the elastic ratio at the initial stages of loading and fall to unity (i.e. the plastic ratio) at the ultimate load, after yielding, plastic spreading and moment redistribution has taken place. The specimen  $100 \times 50 \times 2$  failed in smaller strains, before significant moment redistribution had occurred. Given that the aforementioned specimen achieved very small deformation capacity in the respective 4-point test, this response was anticipated. Note that as will be discussed in Section 4, this is a Class 2 section according to Eurocode<sup>[5]</sup> (i.e. not aimed for plastic design).

# 3 Numerical Modelling

## 3.1 Development of FE models

Finite element models were developed using the general purpose FE software ABAQUS<sup>[27]</sup>. The reduced integration 4-noded shell element S4R suitable for thin or thick shell applications with finite membrane strains was used throughout this study. Mesh convergence studies revealed that a uniform mesh with a size equal to the element thickness for the flat parts of the sections and 3 elements per curved corner region provided a good balance between accuracy and computational cost and were adopted for all simulated sections. To increase computational efficiency, the symmetry with respect to boundary conditions, loading and failure mode was exploited and only half the cross-section was modelled with suitable symmetry boundary conditions applied along the plane of symmetry. The remaining boundary conditions applied were in agreement with the support conditions employed in the tests, whilst the effect of the wooden blocks introduced in the locations of point loads application and support reactions to prevent local bearing failure was simulated by applying the distributing coupling constrain.

Material nonlinearities were accounted for using the von Mises yield criterion and isotropic hardening plasticity. The experimentally derived stress strain curves (see Section 2.2) were converted into the true stress-logarithmic plastic strain format and input into the FE models. Corner strength enhancements brought about by the cold-forming process, by which the sections were produced, were explicitly simulated by assigning the experimentally derived corner properties to the corner regions. In agreement with similar studies<sup>[21]</sup>, the corner properties were assumed to extend into the adjacent flat parts by a width equal to two times the section thickness.

Initial geometric imperfections in the form of the lowest elastic buckling mode shape were assumed to be a suitable representation of the geometric imperfection inherently present in structural members. To this end, an eigenvalue buckling analysis was initially conducted and the obtained lowest buckling mode shapes consistent with local buckling over the points of load application and support reactions were introduced in the subsequent geometrically and materially nonlinear analysis. Three imperfection amplitudes, equal to t/10, t/50 and t/100, where t is the thickness of the simulated section, were considered and based on the validation, the amplitude equal to t/100 was adopted as discussed hereafter. Residual stresses were not explicitly modelled, as their effect is assumed to be reflected in the adopted material properties<sup>[21]</sup>.

# 3.2 Validation

Following the aforementioned modelling assumptions, the numerical results are compared with the experimental ones for the purposes of validation. Table 6 shows the numerical over experimental ultimate load ratios for the geometric imperfection amplitudes considered. It can be observed that the 3-point bending models display the highest sensitivity to the initial geometric imperfection amplitude considered, whilst the 4-point bending models and the continuous beam models are less affected. Typical load-deformation curves f are shown in Fig. 10, where a good agreement between the experimental and numerical response in terms of initial stiffness, ultimate load and post ultimate response can be observed. Overall, best agreement between the numerical and the experimental results has been achieved for the t/100 imperfection magnitude which was adopted for the subsequent parametric studies. Finally, typical experimental and numerical failure modes are illustrated in Fig. 11.

#### **3.3** Parametric studies

Having established the ability of the FE models to accurately replicate the experimental response, parametric studies were conducted to expand the available structural performance data for various geometric parameters, such as cross-sectional slenderness, cross section aspect ratio, moment gradient and loading arrangements. Three cross-sections aspect ratios, namely 1.0, 2.0 and 2.44, four thicknesses, namely 2 mm, 3 mm, 4 mm and 5 mm, two materials, namely austenitic and duplex and two span load cases, as shown schematically in Fig. 12, were considered. The obtained results are analysed and discussed in the following section.

#### 4 **Results and Discussion**

On the basis of the obtained experimental and numerical results, the Eurocode design provisions<sup>[5]</sup> and the Continuous Strength Method<sup>[15, 19]</sup> for the design of simply-supported and continuous beams are assessed.

#### 4.1 The Eurocode design provisions

## 4.1.1 Simply-supported beams

EN 1993-1-4+A1<sup>[5]</sup> adopts the cross-section classification procedure for the treatment of local buckling of stainless steel sections. According to EN 1993-1-4+A1<sup>[5]</sup>, Class 3 sections can reach their yield stress before the appearance of local buckling. The cross-sections which are capable of reaching their full plastic moment capacity are classified as Class 2 sections, while the Class 1 sections are characterized by their capability to reach and maintain their plastic moment capacity with sufficient deformation capacity and can therefore be used in plastic design. The classes of the tested cross-sections are shown in Table 7. Given that the present paper focuses in plastic design of indeterminate structures, most of the specimens have been selected to be Class 1, while only the specimen with nominal thickness 2 mm falling just about to Class 2.

The experimental results of the 3-point and 4-point bending tests are used to assess the current Eurocode slenderness limits for internal elements in compression as well as the codified ultimate predicted capacities. Hence, the ratio of the moment resistance predicted by Eurocode (i.e.  $M_{pl}$  for Classes 1 and 2 sections) normalized by the ultimate moment  $M_u$  is shown in Table 7. As can be seen Eurocode predictions appear rather conservative and largely scattered. This owes to the fact that the strain-hardening exhibited by stocky stainless steel sections is not accounted for by Eurocode.

In Fig. 13(a), the ultimate moment  $M_u$  normalized by the plastic moment  $M_{pl}$  is plotted against the flange slenderness c/tɛ, where c and t the plate's width and thickness respectively and  $\varepsilon = (235/\sigma_{0.2})^{1/2}$ . The Class 2 limit of 35 is also specified, showing that the current limit is acceptable. In order to assess Class 1 limit, the deformation capacity R of the specimens that have failed upon reaching  $M_{pl}$  is plotted against the flange slenderness in Fig. 13(b). The current Class 1 for the part of the specimen subjected to compression is 33. Note that no rules for plastic global analysis given in Eurocode<sup>[5]</sup>; hence there is an absence of codified deformation capacity requirement for Class 1 stainless steel cross-sections. Nevertheless, the deformation capacity requirement R=3 from carbon steel has been considered<sup>[28, 29]</sup>. As can be seen, most of the specimens have reached beyond the required deformation capacity, while the cross-section  $100 \times 50 \times 3$  Duplex for 3-point bending test fell below the deformation capacity requirement of 3. Overall the presented results show that the carbon steel limits could be adopted for stainless steel but further tests are required.

#### 4.1.2 Continuous beams

According to Eurocode<sup>[5]</sup>, the ultimate load that a continuous beam can carry is the one that causes the bending moment of the most heavily stressed cross-section, as determined by elastic analysis, to reach its respective moment resistance (i.e. plastic moment resistance  $M_{pl}$  for Class 1 and 2 sections, elastic moment resistance  $M_{el}$  for Class 3 sections and effective moment resistance  $M_{eff}$  for Class 4 sections). The current provisions account neither for strain-hardening nor for moment redistribution and are expected to lead to overly conservative and scattered design predictions. In order to assess the applicability of traditional plastic design for Class 1 stainless steel sections, a variation of the current Eurocode method for carbon steel structures, which allows Class 1 sections to be plastically designed, assuming rigid-plastic material response, is also assessed herein. This method is expected to lead to improved predictions for Class 1 sections. The suitability of the two aforementioned methods, denoted as "EC3 no moment redistribution" and "EC3 with moment redistribution", is discussed in Section 4.3.

# 4.2 The Continuous Strength Method (CSM)

# 4.2.1 Simply-supported beams

The Continuous Strength Method is a design method for the treatment of local buckling of stainless steel cross-sections, rationally accounting for the significant strain-hardening exhibited by stocky sections. The method is based on the experimentally derived base curve, which relates the non-dimensional slenderness  $\lambda_{cs}$  of a cross section to its deformation capacity  $\epsilon_{csm}$ . Based on the deformation capacity and an assumed elastic-linear hardening material response, the ultimate moment resistance  $M_{csm}$  corresponding to the local buckling strain  $\epsilon_{csm}$  is determined according to Equation (4) for RHS<sup>[15]</sup>

$$\left(\frac{M_{csm}}{M_{pl}}\right)_{i} = 1 + \frac{E_{sh}W_{el}}{EW_{pl}} \left(\frac{\varepsilon_{csm}}{\varepsilon_{y}} - 1\right) - \left(1 - \frac{W_{el}}{W_{pl}}\right) \left(\frac{\varepsilon_{csm}}{\varepsilon_{y}}\right)^{-2}$$
(4)

where  $E_{sh}$  the strain-hardening slope, E the modulus of elasticity,  $W_{el}$  the elastic section modulus,  $W_{pl}$  the plastic section modulus,  $\varepsilon_{csm}$  the maximum attainable strain, which takes place afore the occurrence of local buckling and  $\varepsilon_y$  the yield strain. The method and the relevant expressions are described in [15]. In order to assess the applicability of Equation (4) to the presently studied cross-sections, the results of the 3-point and 4-point experiments are used. The CSM to ultimate moment ratios are reported in Table 7, where the effect of corner strength enhancements has been accounted for according to [25]. The corresponding non-dimensional slenderness  $\lambda_{cs}$ , which is defined as  $(\sigma_{0.2}/\sigma_{cr})^{1/2}$  where  $\sigma_{cr}$  is the elastic critical buckling stress of the cross-sections and has been evaluated from the analytical formuli provided in [31], is also included. As expected, the application of CSM which rationally accounts for the pronounced stain-hardening in the material response of stainless steels leads to more accurate design predictions compared to those of Eurocode.

#### 4.2.2 Continuous beams

Based on the original CSM, the strain-hardening of the most heavily stressed cross-section of an indeterminate structure is accounted for, but no moment redistribution is allowed. Hence, the method is based on an elastic analysis and is expected to provide improved ultimate capacity predictions compared to the Eurocode method.

An attempt was made to extend the CSM to indeterminate carbon steel structures<sup>[30]</sup> and stainless steel structures<sup>[18]</sup>, by allowing for moment redistribution in similar way with the traditional plastic analysis procedure, but adopting an elasticlinear hardening material response rather than the traditional rigid-plastic material response. In order to determine the design strengths of indeterminate stainless steel structures based on the CSM design procedure, the following six steps are required:

- 1. Similar to traditional plastic design, the identification of the location of the i plastic hinges at collapse and the determination of the respective hinge rotations  $\theta_i$  are initially required.
- 2. The maximum strain ( $\epsilon_{csm}$ ) that a cross section can undergo according to its slenderness and the base curve are then evaluated based on Equation (5).

$$\left(\frac{\varepsilon_{csm}}{\varepsilon_{y}}\right)_{i} = \frac{0.25}{(\overline{\lambda}_{cs})_{i}^{3.6}} but \left(\frac{\varepsilon_{csm}}{\varepsilon_{y}}\right)_{i} \le \min\left(15, \frac{0.5\varepsilon_{u}}{\varepsilon_{y}}\right) for \left(\overline{\lambda}_{cs}\right)_{i} \le 0.68$$

$$(5)$$

where  $\varepsilon_{csm}$  is the maximum attainable strain, which takes place afore the occurrence of local buckling,  $\varepsilon_y$  the yield strain,  $\lambda_{cs}$  the non-dimensional cross-sectional slenderness and  $\varepsilon_u$  the strain at ultimate tensile stress.

3. For each collapse mechanism, the rotation demand  $\alpha_i$  of each of the i hinges needs to be determined according to Equation (6).

$$\alpha_i = \frac{\theta_i h_i}{\left(\varepsilon_{csm}/\varepsilon_y\right)_i} \tag{6}$$

where  $\theta_i$  is the relative rotation derived from kinematics considerations for the collapse mechanism considered,  $h_i$  the section height at the considered location,  $\epsilon_{csm}/\epsilon_y$  the corresponding normalized strain ratio at the hinge.

4. The deformation demands in terms of strains at other plastic hinges locations are then assigned relative to that of the critical hinge from Equation (7).

$$\left(\frac{\varepsilon_{csm}}{\varepsilon_{y}}\right)_{i} = \frac{a_{i}}{\alpha_{crit}} \left(\frac{\varepsilon_{csm}}{\varepsilon_{y}}\right)_{criti} \le \left(\frac{\varepsilon_{csm}}{\varepsilon_{y}}\right)_{i}$$
(7)

- 5. Then the cross section bending moment capacity  $M_i$  at each plastic hinge on the corresponding strain ratio  $(\epsilon_{csm}/\epsilon_y)_i$  is calculated based on the Equation (4)
- 6. Finally, the collapse load of the system is determined by equating the external work done by the applied load to the internal work resulting from the hinge rotations according to Equation (8).

$$\sum_{j} F_{j} \delta_{j} = \sum_{i} M_{i} \theta_{i} \tag{8}$$

Both aforementioned methods, namely the "CSM no moment redistribution" and the "CSM with moment redistribution", are assessed in Section 4.3.

#### 4.3 Discussion

In this section, the design methods for the performance and design of stainless steel structures are discussed. In particular, the ultimate capacity predictions determined according to the four design methods outlined above are normalized by the ultimate experimental load and the results are reported in Table 8. Aiming to allow a general overview of plastic design for stainless steel structures, test data reported in the literature are also considered. It can be seen that the Eurocode method, which allows for neither moment redistribution nor strain-hardening yields the most conservative design predictions. Improved design predictions both in terms of accuracy (Mean closer to 1) and consistency (small COV) are obtained for both the variation of the Eurocode, which allows for moment redistribution have to be taken into account, in order to obtain accurate predictions of the observed response and as expected the CSM for indeterminate structures results in most cases in the most accurate design predictions. It should be noted the CSM for indeterminate structures seems better suited for austenitic and duplex grades, which display a high level of strain-hardening whereas the predictions of the ultimate response of ferritic stainless steel continuous beams are overall unsafe.

Similar conclusions are drawn from the results of the parametric studies which are reported in Table 9 and Fig. 14 for the two load cases considered. More conservative design predictions result for stockier sections as can be observed for the EC3 methods; this issue is overcome by the CSM rational exploitation of the material strain-hardening. In both considered structural configurations, significantly improved predicted capacities both in terms of both efficiency and consistency are evident by the CSM considering plastic design. It is noteworthy that similar conclusions were also drawn in a recent

numerical study<sup>[32]</sup> that has rigorously investigated the response of continuous stainless steel beams in five different structural configurations. It can be concluded that the CSM for indeterminate structures sufficiently addresses the issue of both strain-hardening at cross-section level and moment redistribution at structural level.

# 5 Conclusions

The structural performance and plastic design of stainless steels have been studied in this paper. Eight experiments on simply supported beams employing austenitic and duplex stainless steels and four experiments on continuous beams of the same material have been performed. Finite element models were developed and the results of the numerical analyses were compared with the experimental ones. Parametric studies were then conducted in order to investigate the response of continuous beams over a wide range of cross-section slendernesses, aspect ratios and span lengths. Based on obtained results, the Eurocode design provisions<sup>[5]</sup> and the strain-based design approach termed continuous strength method<sup>[15]</sup> were assessed. It was shown that the current Eurocode 3: Part 1.4+A1<sup>[5]</sup> approach significantly underestimates the strength of stainless continuous beams. This is because the formation of successive plastic hinges and moment redistribution in indeterminate structures with adequate deformation capacity, as well as the effect of strain-hardening at cross-sectional level, are not accounted for. Based on the collated test data on continuous stainless steel beams<sup>[17-20]</sup> and the experimental and numerical results of the present study, it was shown that accounting for both strain-hardening and moment redistribution is of paramount importance for the design. To this end, the continuous strength method, which rationally accounts for the local buckling at cross-section level, extended to the design of stainless steel indeterminate structures in order to consider the moment redistribution, provides the most accurate design estimations. Further research is underway to extend the method to the design of pinned based and fixed based stainless steel frames.

## Acknowledgments

The financial support received from the Engineering and Physical Sciences Research Council (EPSRC) under grant agreement EP/P006787/1 is gratefully acknowledged. The authors would like to thank Mr David Price, laboratory technician in the department of metallurgy and materials for his assistance with the material coupon tests.
